Abstract. **Species of *Phytophthora* are ubiquitous in ornamental production resulting in significant crop losses. In Tennessee, national surveys for the sudden oak death pathogen *Phytophthora ramorum* in 2004 and 2005 led to the isolation of *Phytophthora* species causing disease in nursery-grown or handled woody ornamentals or both. Isolates recovered were identified to species using direct sequencing of the internal transcribed spacer and examination of morphological characters. Six known species (*P. cactorum, P. citricola, P. citrophthora, P. nicotianae, P. palmivora, P. tropicalis*) and one newly described species (*P. foliorum*) were recovered from ericaceous hosts. The most common species recovered were *P. citricola* and *P. citrophthora*. Genetic analysis using amplified fragment length polymorphism (AFLP) markers revealed intraspecific genotypic diversity as well as isolates with identical AFLP genotypes from multiple locations across multiple years. This work provides evidence for species and genotypic diversity of *Phytophthora* recovered in Tennessee as well as insight into the movement of individual genotypes in woody ornamental production.**

United States retail nursery sales are valued at $147.8 billion annually and southeastern states account for 10% of this value (Hall et al., 2007). Ericaceous hosts such as azalea, pieris, and rhododendron offer nurserymen attractive high-value crops. Whether produced in ground beds or containers, these hosts are susceptible to at least nine species of *Phytophthora* (Erwin and Ribeiro, 1996; Werres et al., 2001). *Phytophthora cinnamomi, P. cactorum, P. cryptogea, P. lateralis, P. megasperma*, and *P. gonapodyoides* have been reported to cause root rot (Erwin and Ribeiro, 1996; Hoitink and Schmitthenner, 1974; Werres et al., 2001). Species causing twig blight symptoms include *P. cactorum, P. cambivora, P. citricola, P. citrophthora, P. nicotianae*, and *P. ramorum* (Blomquist et al., 2005; Hwang et al., 2006; Schwingle et al., 2007; Werres et al., 2001). Those causing leaf spot or isolated from leaves include *P. citricola, P. citrophthora, P. foliorum, P. ramorum, P. syringae*, and *P. tropicalis* (Gerlach et al., 1974; Hong et al., 2006; Werres et al., 2001). Since the identification and federal regulation of the sudden oak death pathogen *P. ramorum*, there have been a number of monitoring efforts put in place, including nationwide surveys of nurseries and surrounding forested areas (Rizzo et al., 2002; Stokstad, 2004; Werres et al., 2001).

Nursery production facilities with densely grown plants, intensive cropping at the same site, movement of nursery stock, and use of recycled irrigation water provide multiple opportunities for infection by *Phytophthora* species (Ribeiro and Linderman, 1991). Irrigation water used in horticultural production facilities is routinely collected to reduce environmental effects and overall production costs (Bush et al., 2003; Lamour et al., 2003). *Phytophthora* species produce lemon-shaped sporangia in the presence of high moisture or free water that can be dispersed directly or can release motile zoospores (Bush et al., 2003; Lamour et al., 2003; Themann et al., 2002). Free water significantly contributes to the dispersal of *Phytophthora* species and irrigation sources can serve as reservoirs for species like *P. cactorum, P. cinnamomi, P. citricola, P. citrophthora, P. cryptogea, P. megasperma, P. nicotianae, P. syringae*, and *P. tropicalis* (Hong et al., 2006; MacDonald et al., 1994; Yamak et al., 2002). Recovery of *P. citrophthora* and *P. citricola* has been demonstrated to fluctuate seasonally in production facilities (MacDonald et al., 1994).

To date, there have been few reports or characterization of *Phytophthora* species recovered from nursery hosts in the state of Tennessee. During 2004 and 2005, the following species of *Phytophthora* were recovered from ericaceous hosts while testing leaves from Tennessee nurseries for the sudden oak death pathogen: *P. cactorum, P. citricola, P. citrophthora, P. nicotianae, P. tropicalis*, and *P. foliorum* sp. nov. (Donahoo et al., 2006). *Phytophthora* species produce specialized structures allowing for their survival and spread, including a thick-walled sexual spore (oospore), a thick-walled asexual spore (chlamydospore), and an asexual sporangium capable of undergoing cleavage resulting in multiple motile zoospores. The production of oospores can require the interaction of two mating types for some species (heterothallism) (e.g., *P. nicotianae* and *P. tropicalis)*, may be accomplished with a single isolate (homothallism) (e.g., *P. cactorum, P. citricola*, and *P. foliorum*), or may be entirely absent (e.g., *P. citrophthora*).

Identification of *Phytophthora* to the species level was traditionally based on morphological characters. More recently, a variety of nuclear and mitochondrial gene sequences have been used to support, refine, and, in some cases, expand the species definitions in the genus. The internal transcribed spacer (ITS) has proven an invaluable tool in *Phytophthora* species identification (Cooke et al., 2000; Schwingle et al., 2007). ITS sequence data, although useful for distinguishing species, is too conserved to resolve diversity within a species (Kroon et al., 2004; Schwingle et al., 2007). A variety of genetic tools have been used to characterize the diversity of *Phytophthora* isolates within species, including isozymes, restriction fragment length polymorphisms, random amplified polymorphic DNA markers, microsatellites, and amplified fragment length polymorphism (AFLP) markers (Bhat and Browne, 2007; Forster et al., 1990; Gevens et al., 2008; Ivors et al., 2004; Oudemans et al., 1994; Silvar et al., 2006; Vos et al., 1995). We describe the diversity of *Phytophthora* isolates recovered from ericaceous hosts at nurseries throughout the state of Tennessee using a combination of DNA and morphological-based approaches. Our goal was to document the presence of *Phytophthora* species in Tennessee nurseries and to examine the potential mechanisms for dispersal.

Materials and Methods

Fungal cultures. Isolates used in this study are listed in Table 1. All cultures were obtained from leaf samples of azalea, pieris, or rhododendron during the summers of 2004 and 2005. Leaves were collected as part of the Tennessee survey for the sudden oak death pathogen *Phytophthora ramorum*. Leaf tissue from the edge of foliar lesions was plated on corn meal agar (Sigma, St. Louis) amended with PARP (25 ppm pimaricin, 100 ppm ampicillin, 25 ppm rifampicin, and 25 ppm pentachloronitrobenzene) or V8 juice (Campbell Soup Co., Camden, NJ) agar (V8A) (840 mL of distilled water, 163 mL of V8 juice, 3 g of $CaCO_3$, and 16 g of Bacto agar) amended with PARP (Erwin and Ribeiro, 1996). Cultures were subsequently hyphal-tipped to ensure single isolates. Hyphal tipping was accomplished by growing each culture on water agar and then

subculturing a single hyphae from the expanding margin of the culture. Cultures were incubated in the dark at room temperature for 7 to 10 d and then examined microscopically. Cultures were maintained on V8A PARP and were stored long-term at room temperature (25 °C) as colonized agar discs of V8A in sterile water containing two autoclaved hemp seeds (Caten and Jinks, 1968; Erwin and Ribeiro, 1996). Sporangial production was induced by culturing isolates on V8A plates under ambient lighting. Heterothallic species were paired with *Phytophthora capsici* tester isolates CBS 121656 (A1) or CBS 121657(A2) and incubated in the dark for 7 to 14 d. Oospore production and mating type was determined by preparing a "squash mount" and observing under a light microscope.

Mefenoxam sensitivity was assessed by placing a 7-mm agar plug from a 1-week-old, hyphal-tipped derived culture on one 100 × 15-mm plate of V8 agar and two 100 × 15-mm plates of V8A amended with 100 ppm mefenoxam (Ridomil Gold EC, Syngenta, Greensboro, NC). Plates were incubated at 23 to 25 °C for 3 d, and colony diameters were measured. Isolate growth on mefenoxam-amended media compared with control media was classified as sensitive (S, less than 50% of the control) or insensitive (I, greater than 50% of the control) (Gevens et al., 2007; Lamour and Hausbeck, 2000).

DNA extraction and genotyping. Mycelium was grown in V8-PARP broth, lyophilized, and genomic DNA was extracted using Qiagen's DNeasy Plant Mini-kit (Valencia, CA). Genomic DNA from all 67 isolates was subjected to AFLP. AFLP was performed using *Eco*RI and *Mse*I restriction enzymes, adapters, and primers as described previously (Vos et al., 1995). Selective amplifications were done using Eco-AC + Mse-CCC and Eco-AC + Mse-CA primer pairs. Reactions were diluted and labeled in a separate reaction as described previously (Habera et al., 2004). Fluorescently labeled products were resolved on a Beckman-Coulter CEQ8000 capillary genetic analysis instrument (Fullerton, CA). Fragments were confirmed visually and transformed into a binary matrix (1 = present, 0 = absent). The resulting matrix was analyzed with the unweighted pair group method with arithmetic mean as implemented in NTSYSpc2.11a (Rohlf, 2007).

Polymerase chain reaction and internal transcribed spacer sequencing. Polymerase chain reaction (PCR) amplification for the ITS has been described previously and methods are available online (www.phytid.org) (Cooke et al., 2000). PCR-generated amplicons were visually confirmed on 1% agarose gels. Confirmed amplicons were column-purified using a QIAquick PCR purification kit (Qiagen, Valencia, CA). Purified PCR products were submitted for direct sequencing in both directions at The University of Tennessee's Molecular Biology Resource Facility. Sequence trace data were assigned base calls using phred, trimmed, and assembled using CodonCode Aligner (CodonCodes,

Dedham, MA). The consensus sequence from assembled contigs for each individual isolate was used to search the National Center for Biotechnology Information Genbank database.

Results

In total, 67 *Phytophthora* isolates were recovered and characterized in this study. AFLP analysis, ITS sequencing, and subsequent database queries, in combination with morphological characterizations, allowed for identification of the following species: *P. cactorum* (n = 3), *P. citricola* (n = 20), *P. citrophthora* (n = 26), *P. foliorum* (n = 2), *P. nicotianae* (n = 7), *P. palmivora* (n = 1), and *P. tropicalis* (n = 8). Resistance to mefenoxam was observed, but only in *P. citricola* (n = 2) and *P. citrophthora* (n = 4). The presence of distinctive oospore morphologies, sporangial dimensions and pedicel characteristics, and mating type reactions were consistent with the identifications made based on ITS sequencing. The exception was the identification and characterization of a new species, *P. foliorum* (Donahoo et al., 2006).

Species specific clusters were observed with the AFLP data (Fig. 1). The most abundant species recovered was *P. citrophthora*, which appears to be comprised of two subclusters designated A and B. *Phytophthora citrophthora* isolates with identical AFLP genotypes were recovered from operations up to 285 miles apart. Additionally, *P. citrophthora* isolates with identical AFLP genotypes were recovered from both 2004 and 2005 (Fig. 2; Table 1). The second most commonly recovered species was *P. citricola*, and like *P. citrophthora*, two AFLP groups were observed with identical AFLP genotypes recovered from locations up to 150 miles apart and from 2004 and 2005 (Fig. 3; Table 1). Seven isolates of *P. nicotianae* were recovered, three with the multilocus AFLP genotype nic2, two with the multilcous AFLP genotype nic1, and two with unique AFLP genotypes (Table 1). Eight isolates of *P. tropicalis* were recovered, three isolates shared the multilocus AFLP genotype trp1, two exhibited the multilocus AFLP genotype trp2, and two isolates had unique AFLP genotypes. *Phytophthora cactorum* and *P. foliorum* were recovered less frequently. In the case of *P. cactorum*, three isolates were recovered in total, two from one location in 1 year and the third recovered from a different location the next year. Isolates of *P. foliorum* with identical AFLP genotypes were recovered from one location in 2004 and 2005.

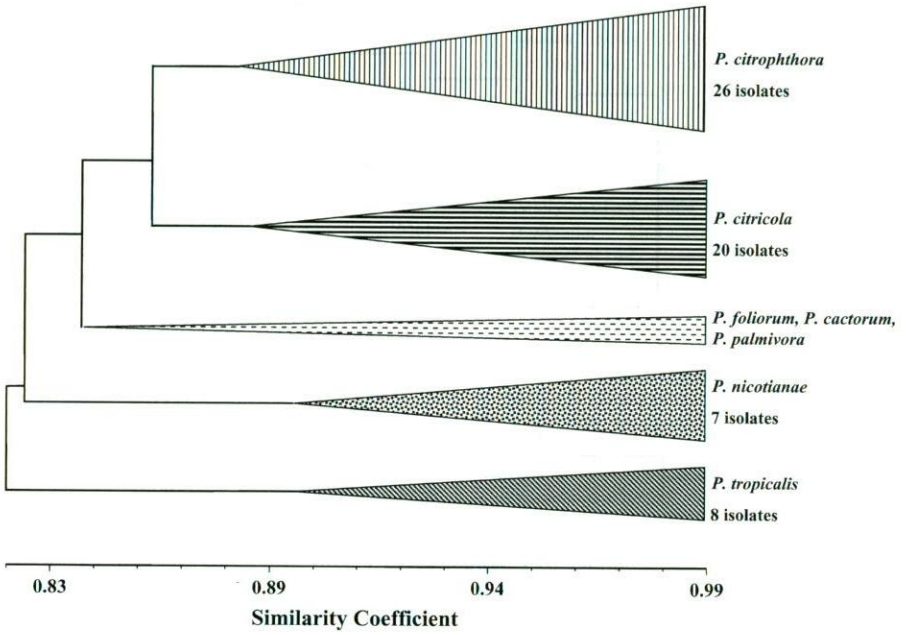

Fig. 1. Genetic similarity of *Phytophthora* isolates recovered from ericaceous hosts. Isolates were analyzed using the selective E-AC/MCCC primer pairs to produce an amplified fragment length polymorphism profile and similarity assessed using the unweighted pair group with mathematical averaging (UPGMA). Isolates/species clustering together have been grouped for illustrative purposes.

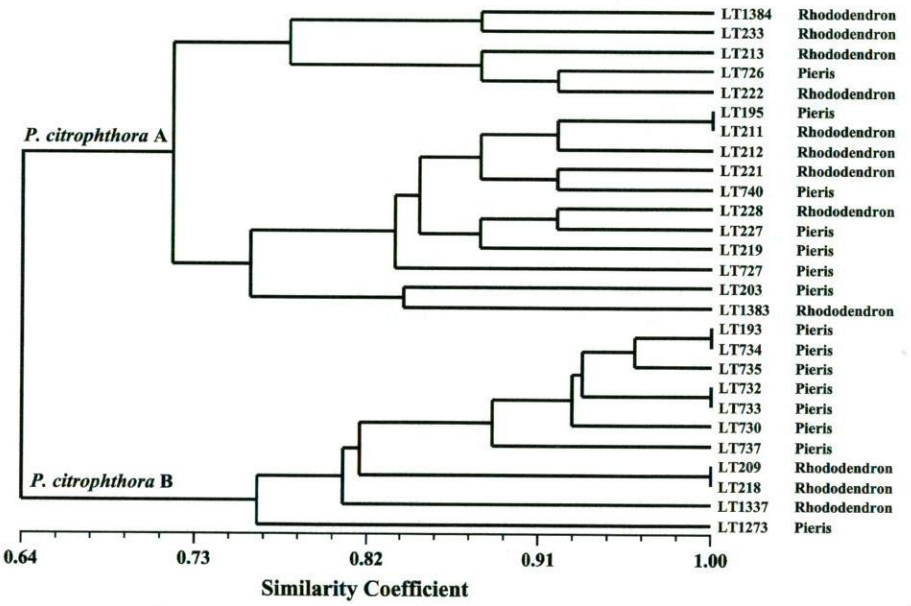

Fig. 2. Genotypic similarity of *Phytophthora citrophthora* isolated form ericaceous hosts in Tennessee based on 37 amplified fragment length polymorphism fragments produced using the E-AC/MCC selective primer combination.

Discussion

Seven *Phytophthora* species were recovered from leaves of nursery-grown ericaceous hosts as part of the sudden oak death survey in Tennessee. The most commonly recovered species were *P. citricola* (29%) and *P. citrophthora* (38%) accounting for 66% of total isolates recovered. This may be the result of sampling bias or may reflect the prevalence of these two species in Tennessee nursery production facilities. Previous reports indicate that *P. citricola* and *P. citrophthora* are commonly associated with container-grown nursery plants or irrigation sources associated with nursery production (Bush et al., 2003; Ferguson and Jeffers, 1999; MacDonald et al., 1994; Schwingle et al., 2007; Themann et al., 2002; Yamak et al., 2002). Similarly, the remaining species identified in this study, although limited in their numbers, have also been recovered from similar hosts/sources (Bush et al., 2003; Ferguson and Jeffers, 1999; Hong et al., 2006; Schwingle et al., 2007). The finding of these species is not surprising because container-grown nursery crops are often handled by multiple facilities both inside and outside of Tennessee during production and the movement of *Phytophthora* between facilities is likely common.

The extent of genetic diversity within species varied with the actual number of isolates recovered. As a result of the limited number of samples, it is difficult to accurately assess the genetic diversity of *P. cactorum, P. foliorum, P. nicotianae*, and *P. tropicalis* in

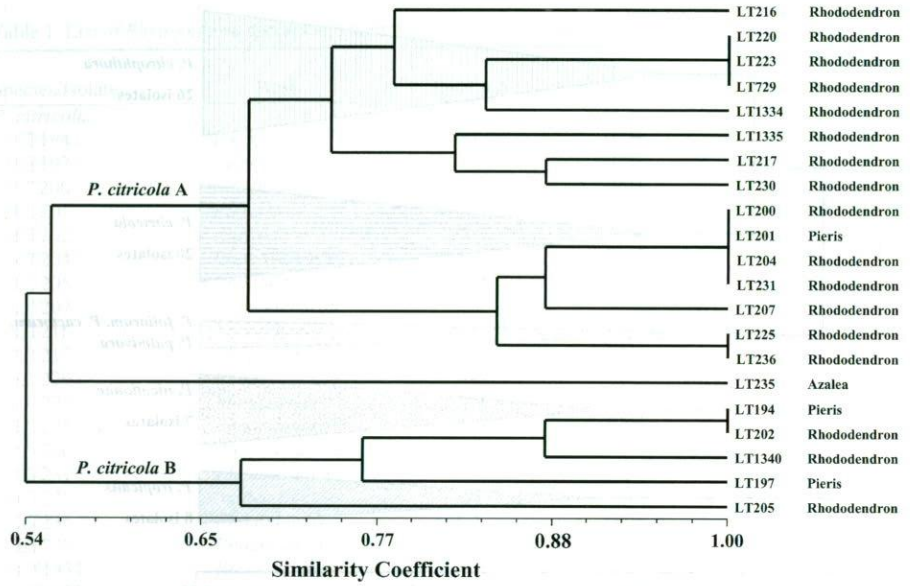

Fig. 3. Genotypic similarity of *Phytophthora citricola* isolated form ericaceous hosts in Tennessee based on 25 amplified fragment length polymorphism fragments produced using the E-AC/MCC selective primer combination.

Tennessee. It has been shown that *P. cactorum* is dispersed throughout southeastern states on strawberry transplants, and because it is homothallic, it is expected to exhibit a low level of genetic diversity (Huang et al., 2004). Populations of *P. cactorum* recovered from strawberries in the United States appear to exhibit greater genetic diversity and are distinct from those recovered in Europe (Eikemo et al., 2004; Hantula et al., 2000; Huang et al., 2004). Additionally, isolates of *P. cactorum* recovered from rhododendron in Germany was found to be similar to both European Union and U.S. strawberry isolates, nonpathogenic on strawberry, and exhibited larger oospores (Hantula et al., 2000). Future studies addressing the diversity among *P. cactorum* isolates from rhododendron in the European Union and U.S. populations may further clarify dissemination of this species.

Isolates of *P. foliorum* from California were found to be identical to the isolates recovered from Tennessee (Donahoo et al., 2006). The seven *P. nicotianae* isolates exhibited one of three AFLP genotypes and a high degree of genetic similarity has been reported for this species (Lamour et al., 2003; Zhang et al., 2003). Little is known about *P. tropicalis* in the continental United States. From our findings here and reports from Virginia and South Carolina, it may be concluded that this species has recently been introduced (Hong et al., 2006; Leahy, 2006). Additionally, *P. tropicalis* isolates recovered in Tennessee can be distinguished from those recovered from cacao or macadamia in the original *P. tropicalis* species description based on nuclear and mitochondrial nucleotide sequences (Donahoo and Lamour, unpublished data).

The larger sample sets revealed considerable diversity within *P. citrophthora* and *P. citricola*. Diversity within *P. citricola* has been documented previously and up to five subgroups have been observed (Forster et al., 1990; Oudemans et al., 1994). A study characterizing *P. citricola* from diverse hosts in California over 30 years suggests that genotypes could be correlated with host and geographical origin (Bhat and Browne, 2007). The authors suggest that the observed genetic diversity may arise by outcrossing similar to what has been observed in the homothallic *P. sojae* (Bhat and Browne, 2007; Bhat and Schmitthenner, 1993; MacGregor et al., 2002). *Phytophthora citrophthora* is not known to complete the sexual stage and is considered sterile (Erwin and Ribeiro, 1996). The mechanisms leading to the observed diversity within isolates of *P. citrophthora* are not known at this time.

Although genotypic diversity was present within all the species studied except *P. foliorum*, we were also able to document the spatiotemporal persistence of isolates carrying identical multilocus AFLP genotypes over 2 years. This may be accomplished through the production of homothallic sexual spores in the case of *P. foliorum, P. cactorum*, and *P. citricola*. In addition, chlamydospores may play an important role in allowing for the persistence of species like *P. citrophthora, P. nicotianae*, and *P. tropicalis*. Furthermore, it is possible that these species of *Phytophthora* are persisting as mycelium in infected host tissues.

An important finding is that all of these isolates were recovered from leaves exhibiting primarily nonspecific brown lesions. In most cases, the leaves were collected from plants that were to be sold within the next weeks or months. This provides a unique opportunity for dispersal both within the nursery production facility and to the environment at large. The sale of contaminated nursery stock allows *Phytophthora* to be dispersed into many different settings and the description of isolates described here may provide a useful baseline for understanding epidemics occurring both within nursery facilities and also in the natural environment (Coffey, 1991).
